CONCLUSION: In this study, we showed that the new calculator, which does not include race or ethnicity, seems to be well adaptable to the Japanese population. Worldwide, the decrease in TOLAC has contributed to the increase in the cesarean delivery rate, which is rising globally. This trend can also be seen in Japan, with <5% of women attempting TOLAC, which is a small percentage when compared with other countries. This calculator can be used to accurately predict individual success rates of TOLAC. Ultimately, it is hoped that this will lead to a reduction in the overall cesarean delivery rate. We also believe that it would be preferable to validate the new calculator in future research that includes additional racial and ethnic groups.

The association of obesity with type I uterine cancer—is this an oversimplification?

OBJECTIVE: Endometrial cancer (EC) is increasing in incidence and mortality rates, possibly due to the rising rates of obesity in the United States. The type I/II EC classification system was first proposed by Bokhman in 1983 following 20 years of personal observations among 366 women and established obesity as a classical risk factor for low-grade EC with a good prognosis. However, more recent pooled analyses suggest that the 2 types share many etiologic risk factors, including obesity. Given the increase in mortality as a consequence of high-risk EC, the relationship between obesity and uterine cancer, as proposed by Bohkman, may be oversimplified. This study aimed to analyze the trend of type I/II EC in the United States as it relates to obesity using national statistics.

STUDY DESIGN: Data were obtained from the United States Cancer Statistics database and the Behavioral Risk Factors Surveillance System survey from 2001 to 2017. The incidence of uterine cancer, histologic type, obesity, and average annual percentage change (AAPC) were calculated using Joinpoint regression. Endometrial histology was classified according to traditional type I (endometrioid grade 1–3) and type II (serous, clear cell, carcinosarcoma) categories.

RESULTS: Over this 17-year study period, 778,891 patients were diagnosed with uterine cancer. Overall, the rate of new uterine cancer cases increased by 0.82% annually (P<.005), leading to an incidence of 24.07 per 100,000 in 2001 as compared with 27.04 per 100,000 women in 2017. The incidence of type I EC remained stable (AAPC, 0.40; P=.061) with a stable incidence of grade I EC (AAPC, −0.48; P=.125) and a
decreasing incidence of grade 2 and grade 3 EC (AAPC, −2.61 and −2.63, respectively; P<0.001). Alternatively, the incidence of type II EC increased by 3.12% annually (P<0.001), leading to an increase of 63% since 2001. Serous carcinoma increased by 4.88% annually (P<0.001). Clear cell and carcinosarcoma also increased significantly (AAPC, 1.02 and 1.51, respectively; P<0.05). For illustrative purposes, we calculated the percentage increase in the incidence of cancer types over the last 17 years in comparison with the year 2001 (Figure). Overall, the proportion of women with obesity also increased significantly from 19.5% to 27.5% during this period (AAPC, 1.5; P<0.001).

CONCLUSION: Utilizing 17 years of data from a national cancer registry, we demonstrated that the incidence of high-risk type II EC has increased, whereas the incidence of low-risk grade I EC has remained stable. In another survey study, we showed the rising incidence of obesity. These findings suggest that the traditional type I/II approach to classifying EC may be oversimplified, particularly as it relates to obesity. Recent studies utilizing The Cancer Genome Atlas classification for EC demonstrated an association between a mean body mass index (BMI) of ≥30 and each of the 4 clusters except for DNA polymerase epsilon gene ultramutated tumors. Furthermore, up-regulation of several genes known to play a role in EC pathogenesis were associated with BMI, suggesting that obesity may create a unique, proinflammatory microenvironment that affects tumor biology at a molecular level. Limitations of the current study include possible information reporting bias, lack of central pathology review, and limited ability to correlate data between multiple databases. Incidence rates are also not corrected for hysterectomy prevalence. However, these trends suggest a potential impact of obesity on the rising rates of type II EC that should be explored further.

Cell-free DNA analysis for noninvasive examination of trisomy: comparing 2 targeted methods

INTRODUCTION: Cell-free DNA (cfDNA) tests for major fetal trisomies are highly effective among high- and low-risk women, with a detection rate of 99.7% for trisomy 21 and a false positive rate of 0.04%. In many countries, cost and complexity are the main obstacles to the implementation of cfDNA tests as first-line aneuploidy screening tests. The Vanadis assay was recently introduced as a cost-effective method with reduced complexity. It provided a high detection rate combined with a low failure rate because samples can be analyzed readily with a fetal fraction (FF) limit of <2%. This is achieved by using novel molecular probe technology that specifically label target chromosomes combined with a new readout format using a nanofilter to enrich single molecules for imaging...
