A healthy 37-year-old woman presented with a 4-day history of a painless but pruritic genital rash and a 2-day history of fever and myalgias. Two weeks earlier, she had had condomless intercourse with a new male partner. Physical examination revealed several umbilicated pustules limited to the genital area (Figure 1). Polymerase-chain-reaction assays of swabs obtained were positive for monkeypox virus. Although classic cases of monkeypox included a febrile prodrome followed by generalized rash, the current outbreak has been characterized mainly by painless anogenital lesions, often without a prodrome. Most reported cases are being observed in men who have sex with men, but this case raises awareness that women are also at risk and gynecologists must be alert to correctly identify the genital lesions and to promptly implement isolation measures. Moreover, the localized genital lesions increase speculation about primarily sexual transmission in the current outbreak.
